ABSTRACT
Present work is aimed to study epidemiological and clinical features of COVID-19 and outcomes from this global infectious public health event through extensive literature survey. This work reveals the causative agent of this disease and number of tests was conducted to identify the virus. Corona Virus is also associated with the severe acute respiratory syndrome corona virus (SARS-CoV), Middle East respiratory syndrome corona virus (MERS-CoV), avian influenza virus, and other common respiratory pathogens. Literature reveals that SARS-CoV-2-infected patients are the main carrier of infection and produce a large quantity of virus in the upper respiratory tract. In future disease of such types can be control system, it is necessary to establish sound public health laws and regulations, conditions, so that it can play a timely and effective role in any future infectious disease outbreak.

KEYWORDS: SARs, corona virus, COVID-19, Symptoms, Wuhan.

INTRODUCTION
In December 2019, a cluster of cases of unexplained viral pneumonia was identified in Wuhan, a metropolitan city in Hubei province, China. Initially, most of the confirmed cases were linked with the Huanan seafood market in Wuhan, where numerous types of live wild animals are sold, including...
poultry, bats, groundhogs, and snakes. To identify the causative agent of this disease, a large number of tests were conducted, which ruled out several etiological agents that may cause similar symptoms, including the severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), avian influenza virus, and other common respiratory pathogens. Finally, a new coronavirus, putatively named 2019-nCoV by the World Health Organization (WHO) on January 12, 2020, was identified as the causative pathogen of this outbreak. On January 20, after a visit to Wuhan, Professor Zhong Nanshan, a SARS intervention specialist, confirmed that 2019-nCoV was spreading between people [1], which led to increased vigilance by the Chinese government and people. At 10:00 on January 23, Wuhan, the birthplace of the disease, declared a general closure to prevent its further spread. However, Wuhan is a major transportation hub located in the central region of the People’s Republic of China with approximately 11 million inhabitants [2], and the period from the end of December 2019 to February 2020 was the time of the “Spring Festival travel rush”. Although the Chinese government made great efforts to control the flow of people, the disease spread rapidly from Wuhan to other cities, as well as other countries, likely through asymptomatic carriers [3]. On January 30, 2020, the WHO declared the outbreak of novel coronavirus a public health emergency of international concern, the sixth public health emergency after H1N1 (2009), polio (2014), Ebola in West Africa (2014), zika (2016), and Ebola in the Democratic Republic of Congo (2019) [4]. The International Committee on Taxonomy of Viruses renamed 2019-nCoV as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and the related pneumonia as coronavirus disease 2019 (COVID-19) on February 12, 2020 [5]. As the disease is highly infectious, “the law of the People's Republic of China on the prevention and treatment of infectious diseases” lists it as a class B infectious disease, and recommends preventive and control measures similar to those against class A infectious diseases. The outbreak is ongoing, and poses a great global challenge.
ETIOLOGICAL CHARACTERISTICS AND ORIGIN OF COVID-19

Coronaviruses were first described by Tyrell and Bynoe in 1966, who isolated the viruses from patients suffering from the common cold [6]. Tyrell and Bynoe called them coronaviruses because they are spherical virions with a core shell and surface projections resembling a solar corona [7]. Coronaviruses are members of the subfamily Coronavirinae in the family Coronaviridae, order Nidovirales. Members of this subfamily were genetically classified into four major genera: Alphacoronavirus, Betacoronavirus, Gammacoronavirus, and Deltacoronavirus [8]. Alphacoronaviruses and betacoronaviruses infect only mammals and usually cause respiratory illness in humans and gastroenteritis in animals. The gammacoronaviruses and deltacoronaviruses predominantly infect birds, but some can also infect mammals [9]. Six types of coronavirus have been identified in humans (HCoVs), including HCoV-NL63, HCoV-229E, HCoV-OC43, HCoV-HKU1, SARS-CoV, and MERS-CoV. The first two belong to the Alphacoronavirus genus and the latter four to the genus Betacoronavirus [10]. SARS-CoV and MERS-CoV can cause severe respiratory syndrome in humans, while the other four human coronaviruses induce only mild upper respiratory diseases in immune competent hosts [11,12]. Coronaviruses did not attract worldwide attention until the 2003 SARS epidemic, followed by the 2012 MERS outbreak and, most recently, the novel coronavirus pandemic.

SARS-CoV-2 was found to be a positive-sense, single-stranded RNA virus belonging to the Betacoronavirus B lineage and is closely related to the SARS-CoV virus [13]. Full-length genome sequences were obtained and indicated that the SARS-CoV-2 genome shares 79.6% sequence identity with that of SARS-CoV [14]. Notably, SARS-CoV-2 infects human lung alveolar epithelial cells through receptor-mediated endocytosis using angiotensin-converting enzyme II (ACE2) as an entry receptor. Attachment to the receptor mediates the subsequent fusion between the viral envelope and host cell membrane, thereby allowing viral entry into the host cell [15, 16].

The origin of the disease has not been determined. As most of the confirmed cases were linked to direct exposure to the Huanan
seafood market [17], it was initially believed that the origin of the virus may have been the seafood market. Based on current sequence databases, all human coronaviruses have animal origins: SARS-CoV and MERS-CoV originated in bats, their natural reservoir, but were transmitted to humans via intermediate host civets and camels, respectively [18]. HCoV-NL63 and HCoV-229E are also considered to have originated in bats, while HCoV-OC43 and HKU1 likely originated in rodents [11, 12]. SARS-CoV-2 is closely related to two bat-derived coronavirus strains, bat-SL-CoVZC45 and bat-SL-CoVZXC21 [13, 19] and is 96% identical at the whole-genome level to bat coronavirus TG13 [7, 14]. This suggests that SARS-CoV-2 may also have originated in to humans via an intermediate host in the Huanan seafood market. Analysis of the genome of a coronavirus isolated from pangolins and SARS-CoV-2 are 99% similar. This suggests that pangolins may be potential intermediate hosts for SARS-CoV-2, and the transmission and evolution path of SARS-CoV-2 may be from bat-humans. However, OnFebruary 20, 2020, the website of the Tropical Botanical Garden of the Chinese Academy of Sciences published an article that suggested that the seafood market may not have been COVID-19, and that SARS-CoV-2 may have been introduced from market. The symptom onset date for December 1, 2019, and no epidemiological link was found between and later cases [17]. Based on factors such as the have appeared SARS-CoV-2, several countries have reported numerous putative source of the infection. The first confirmed COVID-was a patient who had traveled to Wuhan, facilities, and had contact with sick people during his stay in Wuhan [20]. The source of SARS-CoV-2 infection is still unknown. In Italy, meanwhile, where the epidemic is getting worse, “patient zero” has yet to be identified [21]. Greater efforts are required to trace the source of the virus, control it, and clarify its intermediate host, which is of vital importance to controlling the transmission of SARS-CoV-2 [22].

**EPIDEMIOLOGY**

In general, the emergence of an infectious disease comprises three vital elements: infectious source, transmission route, and susceptible population [23]. At present, SARS-CoV-2-infected patients are the main source of infection, producing a
large quantity of virus in the upper respiratory tract during a prodrome period [24]. Because of the mild clinical symptoms during the incubation period, patients can remain mobile and carry out routine activities, leading to the spread of infection. Asymptomatic carriers can also be a source of infection [25]. The incubation period of the disease is 1–14 days, usually 3–7 days, and can even reach 24 days, making it difficult to screen for infections. Additionally, the disease is mainly spread by respiratory droplets and contact. Infections among 14 health workers confirmed the disease's high infectivity and raised concerns that some people may be “super spreaders” of the virus [1]. In a relatively closed environment, aerosol transmission can also occur [26]. Nosocomial transmission is also a severe problem. As of February 12, 2020, a total of 3,019 health workers had been infected, and accounted for 3.83% of the total number of infections [27]. Personal protective equipment (PPE), including fluid-resistant gown, gloves, eye protection, full face shield, and fit-tested N95 respirators, is necessary to maximize the safety of healthcare workers who need to be in contact with critically ill patients with confirmed or suspected SARS-CoV-2 infection [28]. A recent study found that SARS-CoV-2 can be detected in the tears and conjunctival secretions of new coronavirus pneumonia patients with conjunctivitis [29], which suggests that ocular infection may be a source of SARS-CoV-2 transmission. The possibility of fecal–oral transmission also needs to be considered, as viral nucleic acids have been found in fecal samples and anal swabs from some COVID-19–[30]. On February 5, 2020, multiple media outlets also reported that a newborn infant delivered by a woman who had tested positive for SARS-CoV-2 during the epidemic in Wuhan had also tested positive for the virus 30 hours following his/her birth [2]. There is currently no evidence to suggest that SARS-CoV-2 can transmission [31, 32]; however, when delivering a neonate from an infected patient or a person suspected of being infected, neonatologists wear suitable protective equipment. Moreover, the newborns must be isolated as soon as they are suspected of being infected. Although all populations are susceptible to SARS-CoV-2 [26], particular attention directed at vulnerable groups such
as children, health care providers, pregnant women, and the elderly. As of January 29, 2020, a study the clinical symptoms and outcomes for 1,099 COVID-19 patients who had been hospitalized at 552 sites. Their median age was 47 years [33]. SARS-CoV-2 has caused severe illness and death primarily pre-existing conditions such as diabetes and heart disease [34], possibly due to a weakened immune system that permits a faster progression of viral infection. Although children are as likely to be they are less likely to experience severe symptoms [35], which suggests that measures such as school closures may help slow The proportion of pregnant women among the confirmed cases is low; nevertheless, pregnant women are known to be particularly susceptible to respiratory pathogens and severe pneumonia [31]. Furthermore, the occurrence of pneumonia during pregnancy can lead to several adverse obstetric outcomes, such as premature rupture of membranes (PROM) and preterm labor (PTL), intrauterine fetal demise (IUFD), intrauterine growth restriction (IUGR), and neonatal death, and therefore poses great risks to both pregnant women and their unborn children [36, 37]. The mortality rate among pregnant women due to respiratory pathogens is substantially higher than that among ordinary people; for example, the 1918 influenza pandemic resulted in a mortality rate of 2.6% for the overall population, but 37% among pregnant women [38]. Therefore, pregnant women infected with SARS-CoV-2 should be cared for in a health care facility with close maternal and fetal monitoring. In this regard, experiences with illnesses associated with other highly pathogenic coronaviruses, such as SARS and MERS, may also be relevant to SARS-CoV-2, including early isolation, aggressive infection control procedures, oxygen therapy, avoidance of fluid overload, empiric antibiotics, and fetal and uterine contraction monitoring [39].

TRANSMISSION DYNAMICS AND EPIDEMIC STATUS OF COVID-19

Understanding the transmissibility of SARS-CoV-2 remains crucial for predicting the course of the epidemic and the likelihood of sustained transmission [40]. The reproduction number, R, is used to reflect the transmissibility of a virus, and represents the average number of new infections generated
by each infected person, the initial constant of which is called the basic reproduction number, $R_0$: the larger the $R_0$ is, the stronger the transmission potential of the virus [41]. An R-value $>1$ indicates that the outbreak will be self-sustaining unless effective control measures are implemented, while an R-value $<1$ indicates that the number of new cases will decrease over time and the outbreak will eventually stop [42]. Compared with the $R_0$ of H1N1 (1.25) [43] and that of SARS (2.2–3.6) [44], the $R_0$ of SARS-CoV-2 was estimated as 2.2 (95% CI, 1.4 to 3.9) [2], 3.11 (95% CI, 2.39–4.13) [45], and 2.68 (95% CI, 2.47–2.86) [46] by different groups and is significantly larger than 1, indicating that SARS-CoV-2 has a high transmissibility potential and consequently the ability to cause outbreaks. It may be very difficult to contain or control the spread of this virus without adequate prevention and control measures. The effective reproduction number ($R_t$) quantifies the number of infections caused by each new case occurring at time $t$. It is typically lower than that of growing to the effect of control measures in reducing transmission, and the depletion of susceptible individuals during the epidemic; epidemic decay is guaranteed only where $R_t$ is maintained below 1 [47]. The SEIR model, a classic method used to analyze the epidemic trend of an exposed (E), infectious (I), and recovered (R), and has been shown to be predictive for a variety of acute infectious diseases such as [48, 49]. Based on previous studies and the experience gained from epidemic, Wang et al. applied this measures were was assumed to gradually decrease at different phases from a $R_t = 3.1, 2.6, \text{and} 1.9$ to below 1 ($R_t = 0.9 \text{ or } 0.5$), and the estimated number of infections would peak in late February [42]. diagnosed cases in China (Fig. 1), implemented were indeed effective. However, the global situation remains very serious (Fig. 2), and rigorous measures should be maintained so as $R_t$ to an ideal level and control the infection. The WHO in Geneva declared the coronavirus outbreak to be a pandemic on March March 26, 2020, at least 82,078 cases of COVID-19 had been confirmed in China, with 3,298 known deaths, representing a fatality rate of 4%. The outbreak in China seems to be slowing, as evidenced by the daily number of newly diagnosed cases (Figs 1 and 2). The coronavirus outbreak seems to be spreading
faster outside China than inside (Fig. 1B). The WHO reported that more than 462,801 people have been infected worldwide, more than 380,723 of which are outside of China. (WHO; http://2019ncov.chinacdc.cn/2019-ncov/global.html). This does not mean that the outbreak is out of control, and as long as countries take robust action to detect cases early, isolate and care for patients, and track contacts, there is still a chance of containing the virus.

**CLINICAL FEATURES AND DIAGNOSIS OF COVID-19**

Recently, Guan et al. reported that the common clinical manifestations of 2019-nCoV infection among 1,099 laboratory-confirmed cases of COVID-19 included fever (88.7%), cough (67.8%), fatigue (38.1%), sputum production (33.7%), shortness of breath (18.7%), sore throat (13.9%), and headache (13.6%) [33]. In addition, a few COVID-19 patients also showed gastrointestinal symptoms [30], i.e., diarrhea (3.8%) and vomiting (5.0%) [33]. Although studies have indicated that fever is the dominant symptom, some severely or critically ill patients may have moderate, low, or even no significant fever [50, 51]. Therefore, undue emphasis should not be placed on a patient’s body temperature for disease evaluation in clinical treatment and daily screening. Most patients have a good prognosis, while a few are in a critical condition, especially the elderly and those with underlying chronic conditions such as cardiac disease and diabetes [52]. Sepsis is the most frequently observed complication, followed by respiratory failure, acute respiratory distress syndrome (ARDS), heart failure, and septic shock [53].

The first symptoms of COVID-19 are nonspecific. Differential diagnosis should include the possibility of a wide range of infectious (e.g., adenovirus, influenza, parainfluenza, respiratory syncytial virus [RSV], human metapneumovirus [HmPV]) and noninfectious (e.g., vasculitis, dermatomyositis) common respiratory disorders [54]. For health care workers, timely differential diagnosis of patients is important for reducing cross-infection and controlling the outbreak.Computed tomography (CT) has an important role evaluation of COVID-19. Multiple patchy ground glass opacities in bilateral, multifocal lung lesions, with peripheral distribution, are
typical chest CT imaging features in COVID-19 patients, whereas lymphadenopathy, and pulmonary emphysema are uncommon imaging findings [55-58]. Studies have shown that CT has a low rate of missed COVID-19 diagnosis (3.9%, 2/51) [59] and the sensitivity of chest CT was greater than that of RT-PCR (98% vs. 71%, respectively, \( p < 0.001 \)) [60], indicating that CT may be useful as a standard method for the diagnosis of COVID-19. However, CT cannot identify specific viruses or distinguish between viruses al. reported that 20/36 (56%) early-stage patients had a normal CT [61], which suggests that chest CT is unlikely to be COVID-19 infection, especially for patients with early symptom onset. To date, the gold-standard method for the clinical diagnosis of COVID-19 is nucleic acid detection in nasal and throat swab samples or other respiratory tract samples by real-PCR, which is then further confirmed by next-generation sequencing [62, 63]. However, this diagnostic method has several shortcomings, such false-negative rates. Moreover, this method is suitable only to judge the severity and progression of the disease. Additionally, the supply cannot keep up with the demand, and it takes one obtain results, which may be detrimental to the timely treatment of patients.

have issued the 5th version of the diagnosis and treatment plan for COVID-19 [65]. According to the updated criteria, suspected cases with imaging characteristics of pneumonia can be clinically diagnosed as COVID-19 in Hubei province. In this way, patients can receive standardized treatment as soon as possible, so as to further improve the success rate of treatment and contain the spread of the epidemic. Recently, Li et al. developed a rapid and simple point-of-care lateral flow immunoassay that can simultaneously detect IgM and IgG antibodies against SARS-CoV-2 in human blood within 15 minutes. This rapid test has great potential benefit for the fast screening of SARS-CoV-2 infections to prevent virus transmission and assure the timely treatment of patients [66].

**INTERVENTION METHODS**

1. **Potential therapeutic interventions**

At present, there is no specific antiviral treatment recommended for COVID-19, and no vaccine is available. For mildly to moderately ill patients, active symptomatic support remains key for
treatment, such as maintaining hydration and nutrition and controlling fever and cough. For patients with severe infection or those with respiratory failure, oxygen inhalation through a mask, high nasal oxygen flow inhalation, non-invasive ventilation, or mechanical ventilation is needed. Extracorporeal membrane oxygenation (ECMO) can be implemented if all the above methods do not work [67]. Additionally, hemodynamic support is essential for managing septic shock [54], and antibiotics and antifungals may also be required. As corticosteroid therapy is commonly used among critically ill MERS patients [68], short courses of corticosteroids at low-to-moderate doses can be used with caution [69, 70]. As anxiety and fear are common among COVID-19 patients, dynamic assessment strategies should be established to monitor their mental health [71]. Identifying effective antiviral agents to combat the disease is urgently needed. Current guidelines [26] recommend IFN-alpha, lopinavir/ritonavir, ribavirin, chloroquine phosphate, and arbidol as antiviral therapies. IFN-alpha is a broad-spectrum antiviral drug that coronaviruses [72, 73], while lopinavir is a proteinase inhibitor used to treat HIV infection, with ritonavir being used as a booster [74, 75]. In Korea, the viral load of one patient was reduced and clinical symptoms improved with combined administration of lopinavir and ritonavir [76]. open-label trial in China found that lopinavir/ritonavir cotreatment did not significantly enhance clinical improvement, reduce mortality, or diminish seriously ill COVID-19 patients [77]. The efficacy of lopinavir/ritonavir in treating COVID-19 requires further clinical confirmation. Ribavirin, a synthetic guanosine analog and broad-is frequently used for the treatment of SARS and MERS patients 79]. al. [80] reported that, compared with single treatment, a combination of ribavirin and IFN-beta inhibited SARS-CoV replication concentrations. However, the use of ribavirin is associated with significant toxicity, including hemolysis and reduced hemoglobin levels ribavirin should be used with caution as a treatment for COVID-that chloroquine phosphate, widely used to treat malaria and autoimmune diseases [82, 83], may have some COVID-19 associated pneumonia, with acceptable safety [84-86]. Arbidol, Russian-made small indole-
derivative molecule, is used for prophylaxis and treatment of influenza and other respiratory viral infections [87, 88]. Deng et al. combined with lopinavir/ritonavir might delay the progression of lung lesions and reduce the viral load in COVID-19 patients. Nearly all the above-drug options are associated with the treatment of SARS, MERS, viruses and additional randomized, prospective studies are still needed to determine their efficacy against COVID-19. There are many other antiviral drugs with potential as treatment options against COVID-19. Remdesivir, a nucleotide analog prodrug currently in clinical trials for the treatment of Ebola virus infections [90], is a promising compound [91], since preclinical studies have suggested that remdesivir may be effective for both prophylaxis and treatment of HCoV infections [54, 92, 93]. Elfiky [94] found that sofosbuvir was a potent inhibitor of COVID-19 RNA-dependent RNA polymerase (RdRp). Oseltamivir is a neuraminidase inhibitor indicated for the treatment of influenza [95, 96]. Nafamostat can block MERS-CoV infection in vitro [97] and is potentially applicable to the treatment of Ebola virus disease [98]. Favipiravir is a broad-spectrum antiviral that has shown promise for treating influenza [99] and may also be effective against the Ebola virus [100]. Nitazoxanide is both an antiprotozoal agent and a first-in-class broad-spectrum antiviral agent [101] that may be useful for the treatment of MERS infections [102]. It has recently been suggested that treatment with angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor 1 (AT1R) inhibitors might reduce the pulmonary inflammatory response in COVID-19 patients [103]. Monoclonal antibody therapy [104] and convalescent plasma [105] also have potential as therapeutic interventions to treat COVID-19. Chinese traditional medicines, such as ShuFengJieDu [106, 107] and Lianhuaqingwen capsules [108, 109] can also aid in the prevention and treatment of infectious respiratory diseases such as influenza A (H1N1). Radix astragali (Huangqi), Radix glycyr rhizae (Gancao), Radix saposhnikoviae (Fangfeng), Rhizoma Atractylodis Macrocephalae (Baizhu), Lonicerae Japonicae Flos (Jinyinhua), and Forsythiae Fructus (Lianqiao) have long been used for the prevention of contagious
respiratory viral diseases, indicating that Chinese herbal formulas may also be treatment options for COVID-19 [110, 111]. In addition, fighting viruses with antibiotics is often overlooked [112], and drugs such as teicoplanin [113, 114] and ivermectin [115-117] may also be useful to treat COVID-19.

2 Non-pharmaceutical interventions

Currently, the therapeutic strategies employed to deal with COVID-19 are only supportive, and strategy. On January 23, 2020, the local government of Wuhan announced the suspension of public transport services, and closed airports, railway stations, and highways in the city. Since then, many other cities have also begun [118]. Transportation quarantine has been comprehensively strengthened in passenger stations and other public places, and temperature tests have been carried out to screen for potential cases of COVID-19. In addition, strict monitoring measures have been put in place in various regions for returnees, especially those returning from Hubei province or with suspected exposure to the infection. The Chinese government has also employed numerous public gatherings, closing 23]. The Chinese government attached great importance to the COVID-funds for the purchase of drugs, and protective equipment, and [119]. Rapidly sharing scientific information is an effective means of COVID-19 [120]. However, the internet dissemination of misinformation [121], and governments information and clarifying ‘fake news’ to this new infection. SARS-CoV-2 might be difficult. However, many simple and low-cost interventions, such as handwashing [122, 123], may reduce the transmission of epidemic-causing respiratory viruses. Wearing masks as a public health intervention may also help break the transmission link with apparently healthy infectious sources [124-126]. At present, for the public, the most direct and effective way to prevent the spread of the disease is to take protective measures, including improving personal hygiene, wearing a medical mask, having enough rest, maintaining ventilation, and avoiding crowds.

DISCUSSION

Coronaviruses have been associated with several outbreaks of infectious disease in humans, including SARS in 2002–2003 and MERS in 2012. According to the WHO, a total of 8,098 people worldwide became
sick with SARS during the 2003 outbreak, 774 of whom died. After the SARS outbreak, MERS became the second coronavirus to cause a serious global public health crisis. From 2012 to 2018, the WHO recorded 2,220 laboratory-confirmed cases, resulting in at least 790 deaths [127]. According to the current statistics, the number of COVID-19 infections and deaths far exceeds that of SARS and MERS and is still increasing. The reservoir host of the 2003 SARS virus was thought to be the Asian civet (*Paguma larvata*). The focal point of host-to-human transmission was thought to be the live animal market in Guangdong province in China, much like the ongoing COVID-19 outbreak [128]. The COVID-19 outbreak is another reminder of the ability of viral spill-over from animals to cause severe disease in humans. While it is unclear whether the Huanan seafood market is the source of the current outbreak, a total ban on the illegal wildlife trade is imminent. The epidemic situation in China has improved. As this is a sudden and new infectious disease, many limitations, such as the lack of administrative capacity, insufficient financial support, low professional quality of some personnel, and inadequate equipment, as well as other inadequacies of the national disease control system, have seriously affected the effective control of COVID-19 [129]. To modernize the disease control system in the future, it is necessary to establish sound public health laws and regulations, conditions, so that it can play a timely and effective role in any future infectious disease outbreak [130].

The SARS-CoV-2 epidemic continues. In the last few months, substantial progress etiology, and clinical treatment. The Chinese government has taken a series of timely and effective measures to contain the spread of the epidemic in China. However, the global situation is very serious, and numerous questions remain unanswered. It will take the combined efforts of all the countries in the world for the epidemic to ultimately subside. However, the coronaviruses identified to date might be only the tip of the iceberg, and other novel and severe zoonotic events close monitoring and vigilance remain a top priority for health workers and health authorities. We are not only dealing with the current learning from this experience, so as to establish an effective
emergency response system to prevent similar crises in the future.
